SUPPLEMENTS TO THE MONTHLY WEATHER REVIEW

During the summer of 1913 the issue of the system of publications of the Department of Agriculture was changed and simplified so as to eliminate numerous independent series of bureau bulletins. In accordance with this plan, among other changes, the series of quarto bulletins—letters from A to Z—and the octavo bulletins—numbered from 1 to 44—formerly issued by the U. S. Weather Bureau have come to their close.

Contributions to meteorology such as would have formed bulletins are authorized to appear hereafter as Supplements of the MONTHLY WEATHER REVIEW. (Memorandum from the Office of the Assistant Secretary, May 18, 1914).

These supplements comprise those more voluminous studies which appear to form permanent contributions to the science of meteorology and of weather forecasting, as well as important communications relating to the other activities of the U. S. Weather Bureau. They appear at irregular intervals as occasion may demand, and contain approximately 100 pages of text, charts, and other illustrations.

Owing to necessary economies in printing, and for other reasons, the edition of SUPPLEMENTS is much smaller than that of the MONTHLY WEATHER REVIEW. SUPPLEMENTS will be sent free of charge to cooperating meteorological services and institutions and to individuals and organizations cooperating with the bureau in the researches which form the subject of the respective supplements. Additional copies of this SUPPLEMENT may be obtained from the Superintendent of Documents, Washington, D. C., to whom remittances should be made.

The price of this Supplement is 35 cents.

INTRODUCTION

The meteorological data obtained by the two Byrd Antarctic Expeditions, 1928-30 and 1933-35, have been published in *MONTHLY WEATHER REVIEW SUPPLEMENT* 41 (1); the present volume is devoted to tabular and graphical summaries of these data.

Both expeditions based at exactly the same location, Little America. In 1934 a secondary meteorological station, Bolling Advance Base, approximately 100 geographical miles due south of Little America, was occupied alone by Admiral Byrd for 6 months during the dark season. The coordinates of the stations were:

LITTLE AMERICA

Latitude $78^{\circ}34'06''$ S.; longitude $163^{\circ}55'58''$ W.
Height of barometer above sea level, 30 feet.
Height of surface above sea level, 46 feet.

BOLLING ADVANCE BASE

Latitude $80^{\circ}07'30''$ S; longitude $163^{\circ}55'$ W.
Height of Advance Base above sea level, computed by method 1=246 feet; by method 2, 280 feet (for the methods of computing the altitude of Advance Base, see (1), p. 7).

Much of the work of preparing these statistical tables was carried on by the writer during his spare time; and assistance was provided by the Works Progress Administration, Massachusetts State Project No. 14344, for which acknowledgment is gratefully made.

Although it has not been possible to check all of the tables presented herein, many of them have been checked, especially those giving the direction and velocity of the wind at upper levels as computed from the pilot-balloon ascents. The author is greatly indebted to R. J. Smith of the Weather Bureau for his valuable assistance in this connection.

EXPLANATION OF THE TABLES

1. TEMPERATURE SOUNDINGS

Instruments and methods.—With few exceptions, most of the free-air temperature soundings on the first expedition, 1928–30, were made with kites. These kites were of the standard type as formerly used by the United States Weather Bureau and are described in (1A). The meteorographs, two in number, were of the Marvin type, also described in (1A).

The kite equipment consisted of a special lightweight hand reel, and a large quantity of piano wire. To shelter the kite equipment, a small house was built with walls of snow blocks and a roof of tarpaulin supported by bamboo poles. Some warmth was furnished by burning seal blubber in an improvised stove. It was intended to make kite ascents throughout the entire period during which the base at Little America was occupied; and it is very unfortunate that during a blizzard in March 1929 a box containing essential kite parts was lost under the snow and the ascents could not be begun until September 1929 when the replacements for the lost parts were finally finished. The instruments were tested and calibrated several times at Little America.

Because of the difficulties encountered on the first expedition in using kites, a small plane was used instead on the second expedition, 1933–35. An autogyro was taken along primarily for the purpose of making temperature soundings; the advantages of this type of plane were the small fuel consumption, the relatively small amount of work required to prepare it for flight, and the ease with which it could take-off and land; its chief disadvantage lay in its relatively low ceiling, the maximum altitude it could attain being about 3 km. The ascents with the autogyro were begun on September 1, 1934, but unfortunately just after the take-off for the 11th ascent on September 25, the plane got out of control, crashed to the surface, and was completely wrecked. Since it had been planned to make daily ascents when the weather permitted and since the other planes were not ready for flying at that time, the loss of the autogyro was a serious blow to the meteorological program. It was not until November that the ascents could be continued and even then these could not be carried out with the regularity which was desired, since the two remaining planes were usually needed for other purposes and required more work to prepare for a flight and more fuel to operate.

On the second expedition, three aerometeorographs of the Friez type were used, which are described in (2). In two of these, the clocks did not perform satisfactorily at low temperatures, with the result that almost all of the soundings were made with the remaining one. As on the first expedition, these instruments were re-tested and re-calibrated at Little America, even though this had been done in the United States before the departure of the expedition.

In using the autogyro, the aerometeorograph was suspended in a metal frame attached to the wing strut. In using the Pilgrim and large Condor planes, the instrument was enclosed in a small case which was suspended inside the plane at the rear of the cabin. This arrangement not only reduced the vibration of the instrument to a mini-

mum but also made it possible to change the record sheets when long flights were made from the base at Little America, an aerometeorograph record being obtained on nearly all such flights. To provide for proper ventilation of the aerometeorograph, there were two air vents in the case in which it was contained, one at the front and another at the rear. From a vent on the top of the fuselage, the outside air was led to the forward vent in the case containing the aerometeorograph by means of a tube of windproof cloth; the air coming in through the forward vent then circulated past the instrument and escaped through the vent at the rear. The air circulation provided in this way seemed quite ample and satisfactory, the velocity of flow past the instrument amounting to perhaps 10 or 12 miles per hour. This same method of installing the meteorograph in the plane was also used in 1929.

There is one circumstance in connection with this method of "exposing" the aerometeorograph which should be mentioned. Sometimes when the instrument was installed in the plane before the take-off, the temperature inside of

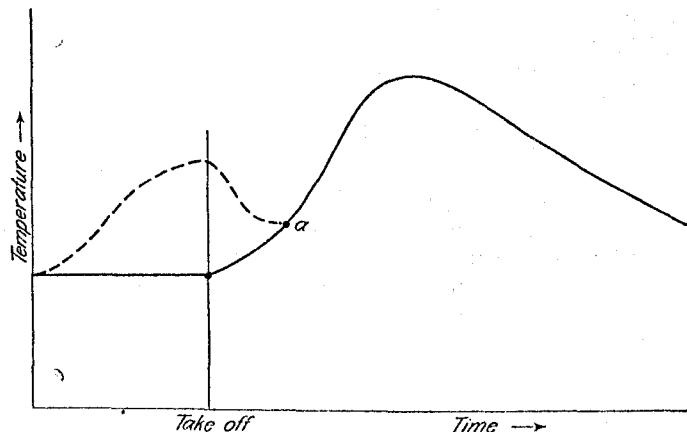

FIGURE A.—Effect on aerometeorograph record of heating before take-off. (Schematic).

the plane became considerably higher than that of the outside air as a result of insulation on the fuselage. Consequently, when the instrument was installed in the plane prior to the take-off, it recorded a temperature higher than that of the outside air, and it was not until a short time after the take-off that the recorded temperature came into equilibrium with the free-air temperature. Usually a surface inversion was present; the resultant effect is illustrated in figure A.

Owing to the vigorous flow of the outside air past the meteorograph immediately after the take-off, the equilibrium point A, judging from the records, was probably attained within a short time, say within 2 or 3 minutes after the take-off, corresponding to an altitude of about 200 or 300 meters. It is thought that in most cases the first significant level was at a higher altitude, where this effect was no longer present, although it must be admitted that in some cases when the heating effect at take-off did occur, the temperature changes within the first few hundred meters were lost.

Results of the kite and airplane ascents.—The results of all the kite and airplane ascents are shown graphically in figures 1 to 85. The soundings are numbered the same as in the previous volume of data (1). With each curve is given the date, year and time of take-off or landing, as the case may be, and also the time of the pilot-balloon ascent nearest in time to that of the temperature sounding. The direction and velocity of the surface wind at the beginning of the sounding are given to the left; the other wind data are the direction and velocity of the wind at the standard levels as determined from the pilot-balloon observation. The significant levels are indicated by circles. In cases where the records of the kite ascents permitted, both the ascent and descent have been worked out. The curves include several soundings which, although not taken right at the base, were within a 100-mile radius and can probably be considered as representative of conditions at Little America. Soundings of this nature have been used in the monthly means.

An aerometeorograph record was obtained for practically all of the airplane exploration flights; and the portions of the record obtained just after the take-off and before the landing, when the plane was not too far removed from Little America, have been considered as soundings even though they do not extend to very high altitudes. During some of the flights the plane underwent considerable variations of altitude at positions fairly far removed from Little America; these portions of the record have been regarded as soundings but have not been included in the monthly charts nor the monthly means.

Regardless of the year in which they were made, the soundings have been grouped together according to months and are shown graphically in figures 86 to 90, inclusive. Since there are relatively few observations at the higher levels, to derive a mean monthly distribution of temperature extending as high as possible and still fairly representative, a method of differences was used at the higher levels, the mean vertical temperature distribution for the different months being computed as follows:

September.—Arithmetic mean to 2,500 m.; extended to 3,000 m. by using the mean of the temperature differences between succeeding standard levels.

October.—Arithmetic mean to 750 m.; extended to 1,500 m. by using the mean of the temperature differences between succeeding standard levels.

November.—Arithmetic mean to 1,000 m.; extended to 3,000 m. by using the mean of the temperature differences between succeeding standard levels.

December.—Arithmetic mean to 2,500 m.; extended to 3,000 m. by using the mean of the temperature differences between succeeding standard levels.

January.—Arithmetic mean to 3,000 m.; extended to 4,500 m. by using the mean of the temperature differences between succeeding standard levels.

In some cases where a sounding did not quite reach the next standard level, a short extrapolation has been used. Some of the soundings are descents, and we therefore have instances of two soundings on the same day, usually not a very long time apart. To avoid giving undue weight to such days, these soundings have each been given a weight of one-half where they are used together. The following are the soundings in groups of two which when used together have each been given a weight of one-half.

In cases where only one sounding of the group is used, that sounding is given a weight of one. The above method of weighting has also been applied in forming the numbers of observations at the various standard levels.

The mean vertical temperature distribution, computed as stated above, is given in table 1, with the numbers of observations at the different standard levels in table 2.

Corresponding curves are given in figure 91 by the full lines and are indicated in the monthly charts by heavy lines. From table 2 it is seen that the number of observations drops off quite rapidly with altitude. This is mainly the result of the fact that the ascents by airplane have been combined with those by kite, and the latter did not extend to very high altitudes.

October	November	December	January
13 and 14	19 and 20 24 and 25 26 and 27 32 and 33 38 and 40 41 and 42 44 and 45 46 and 47	48 and 49 51 and 52 56 and 57 58 and 59 60 and 61 63 and 64 68 and 69 70 and 71	76 and 77 78 and 79

It is possible to derive a mean vertical temperature distribution in a way that will emphasize any given general characteristics exhibited by the majority of the individual soundings. This procedure has been used by Sverdrup (3). In September, for example, nearly all the soundings show a layer next to the surface having a rapid increase of temperature with altitude, and an adjacent layer above in which the temperature increases still further but at a smaller rate. To compute mean values so as to emphasize this characteristic temperature distribution, we may calculate the following values: the mean temperature at the surface t_0 ; the mean height of the layer with rapid temperature increase h_1 , and the mean temperature at the top of this layer t_1 ; the mean height h_2 of the super-adjacent layer having a smaller rate of temperature increase, and the mean temperature at the top of this layer t_2 . Only those soundings showing the given characteristic have been used in the computation; and the mean temperatures for succeeding standard levels have been obtained by applying to these soundings the same procedure used in the first method for getting the mean temperature distribution. Out of a total of 9 soundings during September 1929 and 1934, all but one showed the characteristic inversion; soundings 1 and 4 have not been counted since they do not extend high enough to show this property. An examination of the soundings for the months October, November, December, and January shows that the majority of the soundings in each of these months also exhibit a surface inversion of temperature, as brought out more clearly by the following tabulation; in this tabulation those cases in which there was a small isothermal layer next to the surface, with an inversion immediately above, have been regarded as surface inversions:

Month	Total number of soundings	Number of soundings with surface inversion	Number of soundings without surface inversion
October.....	5	5	0
November.....	23	18	5
December.....	18	13	5
January.....	5	5	0

Thus, during the months from October to January, the majority of the soundings in each month are characterized by a surface inversion of temperature, and use will be made of this fact to compute the mean temperature distributions by a second method. In using this method only those soundings having the characteristic surface

inversion will be used and the following values will be computed: The mean temperature at the surface t_0 ; the mean height of the inversion layer h_1 , and the mean temperature at the top of this layer t_1 ; the mean temperature for succeeding standard levels is obtained by applying to these soundings the same procedure used in the first method. The resulting mean temperature distributions as computed by this second method are given in table 4 and are represented graphically in figure 91 by the dotted lines.

From the soundings represented in figure 86, we see that every one of these has a large surface inversion of temperature. Disregarding 1 and 4 which do not extend high enough, all of the soundings, except 10, show a characteristic stratification of temperature such that there is a rapid increase in temperature in the layer just above the surface, followed by a less rapid increase in the layer above. After the highest temperature is reached there is then a fairly uniform decrease in temperature. The altitude of the top of the inversion where the highest temperature is reached, which can be regarded as the thickness of the cold layer, is indicated by the figures in table 7.

In table 6 are given the mean lapse rates, with low and high wind velocities, from the surface to the first significant level; that is, in the very lowest layer. In the low velocity group are included those cases when the surface velocity at the time of the sounding was less than 5.0 m. p. s.; the high-velocity group contains the cases when the surface velocity was equal to or greater than 5.0 m. p. s., and it is seen from table 6 that this gives nearly the same number of cases in each group when the total number of soundings is considered. We do not have data for the whole year, since the soundings were made only during the period September to January, inclusive. The values for September have been worked out separately, since this is the coldest month during which soundings were made and serves to represent winter conditions. October and November have been combined together and may be taken as representative of spring conditions; while the combination of December and January will serve to indicate summer conditions.

The mean vertical distribution of pressure and temperature at Little America, and at Cape Evans for November and December, are given in table 10; and that for September at Little America, and August at Cape Evans, in table 11. The mean values for Cape Evans have been computed from the data given by Simpson (9). The mean temperature curves are shown in figures 95 and 96. Since the values for Cape Evans are based on a small number of ascents, and also because these were made in a different year (1911), it is difficult to say how much weight can be given to the comparison of the curves in figures 95 and 96.

2. THE PILOT-BALLOON ASCENTS

Methods and apparatus.—The balloons were the ordinary 6-inch balloons used by the United States Weather Bureau, weighing approximately 30 grams. They were filled with hydrogen, to a free lift of 140 grams and a resulting ascensional rate of 180 meters per minute. The supply of hydrogen was contained in metal cylinders such as ordinarily used for the purpose.

After dark, a small paper-lantern containing a lighted candle was suspended from the balloon. This method of illumination was quite satisfactory.

For filling and observing the balloon, a small room was excavated in the snow near the junction of the tunnel and the Administration Building. An opening about 5 feet square was cut through the ceiling of the room to the snow surface, to allow the balloon to be released and observed. This opening was boxed in with a wooden frame, the top of which projected slightly above the snow surface. A light cover, made of a wood frame covered with canvas, was fitted over the top of the opening and could be removed or replaced from beneath. A platform for the theodolite and observer was erected under the opening so as to bring the theodolite telescope level with the top of the frame.

Considerable difficulty was experienced on the first expedition by the formation of frost on the theodolite lenses while the pilot balloon was being observed, especially in the colder weather when the vapor in the observer's breath and probably also the moisture from his face condensed on

the cold glass of the lenses. During the winter night, when lanterns were suspended from the balloon this formation of frost would after several minutes make it impossible to see the lantern, and the observer would have to stop observing and scrape the two lenses with a small piece of wood once or twice a minute; this, of course, made it difficult to keep the lantern in the field, and in some cases was responsible for losing the balloon entirely.

To remedy this trouble, two simple but effective heaters were devised during the second expedition. The heater for the object lens consisted simply of a 15-watt electric light bulb. This bulb was placed under the theodolite barrel, with the end of the bulb flush with the object lens. Around the bulb and the barrel was then wrapped a single layer of asbestos-covered wire mesh, and around this was wrapped a number of turns of ordinary friction tape. The asbestos-covered wire mesh prevented the bulb from burning the tape, and the tape kept the bulb securely fastened to the barrel of the theodolite, at the same time completely protecting it from drift and snow and preventing the escape of any light. Leads were run from the bulb socket to the building nearby and tapped into a 110-volt line. The heat from the lighted bulb heated the end of the theodolite barrel near the objective, and this in turn heated the lens by conduction, preventing any frost formation whatever.

This type of device was too bulky for the eyepiece and would not give the observer an unobstructed view of

the theodolite scales; hence, a resistance type heater was used here. It consisted of a piece about three-fourths of an inch long cut from a resistance unit made of resistance wire wound on a ceramic tube. With a little filing of the inside of a tube, it was easily made to fit on over the eye-piece. Leads were run from this resistor into the building where they were connected to a 6-volt storage battery. Although the ceramic tube was an insulator, it was quite thin, and sufficient heat got through it to heat the eye-piece tube which in turn conducted heat to the lens. No frosting of the lenses was experienced after these heaters were put into use.

The ascents were carried out by two persons: The observer stationed on the outside followed the balloon with the theodolite, and at minute intervals read the angles and relayed these figures to the recorder inside the nearby building by means of a telephone headset.

Mean vertical distribution of the wind.—Mean results from the pilot-balloon ascents give the following information for the different standard levels:

Number of observations.

Mean wind direction.

Mean wind velocity.

Resultant wind direction.

Resultant wind velocity.

Stability.

The north-south and east-west components of the resultant wind velocity.

In some cases where the ascent did not quite reach the next standard level a short extrapolation was used, as follows:

From 0 to 750 m., no extrapolation; from 990 to 3,000 m., extrapolation of 110 m. allowed.

From 3,000 to 5,000 m., allow extrapolation of 180 m.

For over 5,000 m., allow extrapolation of 250 m.

The mean wind direction, sometimes referred to as the frequency-resultant direction, is computed by a method equivalent to Lambert's formula (4) by using directions from the individual ascents to the nearest sixteenth compass division and weighting these according to the frequency of their occurrence.

The mean wind velocity is obtained by computing the arithmetic mean of all the velocities, including calms, regardless of direction.

The resultant wind direction, sometimes also called the direction of resultant movement, is likewise computed from Lambert's formula by using the directions of the individual ascents to 16 points, but by weighting these according to their velocities instead of their frequency as in the computation of the mean direction.

The resultant velocity is obtained by dividing the resultant wind movement by the total number of observations.

The stability is computed by dividing the resultant velocity by the mean velocity and expressing this ratio as a percentage; this figure gives some indication as to the steadiness of the wind. Thus, if the winds were equally distributed among the different directions and also had the same velocities, the resultant velocity and hence the stability would be zero. On the other hand, if the winds blew constantly from the same direction, the resultant and mean velocities would be the same and the stability would have a value of 100.

For the north-south components of the resultant wind velocity, a plus sign indicates that the component is

from the north and a minus sign that it is from the south; for the east-west components, the plus sign indicates that the component is from the west and a minus sign that it is from the east.

The results of the pilot-balloon ascents for the individual months are given in table 11A, and the results by months, when the data of both expeditions are combined, are given in table 12. Most of these combined monthly results are thus based on 2 months of observation, while January is based on 3. February and March have only a single month of observation each, since on the second expedition it was impossible to start the pilot balloon work before April.

Table 13 gives the results when the ascents are grouped, using combined data, according to the four seasons, summer, autumn, winter, and spring. Here, and also in all other portions of the report, the term "combined data" means that the data of both expeditions, 1929-30 and 1934-35, have been combined and used together. The definitions of the four seasons which are used here and throughout the work are as follows:

Summer: December, January, February.

Autumn: March, April, May.

Winter: June, July, August.

Spring: September, October, November.

Results are also given for the combination of the three coldest months, July, August, and September; for the light and dark season; for each year separately; and for both years combined. The light and dark seasons are each taken to consist of a 6-month period as follows:

Light season: October, November, December, January, February, March.

Dark season: April, May, June, July, August, September.

Results are not given for levels having less than three observations.

During the first expedition, 1928-30, ascents were made over a 13-month period, from January 1929 to January 1930, inclusive. During the second expedition, 1933-35, ascents were made during 10 months, from April 1934 to January 1935, inclusive. A few ascents made in February 1930, March 1934, and February 1935, have not been included in tables 12 and 13, but are used in table 14 which gives the mean and maximum altitude of the ascents for the different months. These mean altitudes may seem relatively low, but it must be remembered that they include many ascents in which the balloon entered low clouds, a circumstance which is quite effective in lowering the mean values. Mean altitudes are also given for only those ascents made during clear weather; these, of course, are considerably higher than the mean value based on all ascents. The highest altitude reached was 13,950 m. on September 17, 1934.

All of the results in tables 11A, 12, and 13 are directly computed mean values; no attempt has been made to use any kind of difference method even though the decrease in the number of observations at the higher levels would probably justify something of this kind. The results in table 13 are shown graphically in figures 97 to 106, which give curves for the vertical distribution of the resultant and mean velocity, and the resultant and mean direction.

That the decrease in the east component in the cold season is real, and not the result of having made the pilot-balloon ascents during particular weather types, is sub-

stantiated by the results of the hourly surface-wind observations given in the following table:

Mean surface wind direction

	Summer	Winter	3 coldest months
From hourly values-----	S.50°E	S.11°E	S.7°W
From pilot-balloon ascents-----	S.26°E	S.5°E	S.16°W

The *mean* direction, as computed from the hourly values, shows the decrease in the east component from summer to winter and also the absence of any east component during the 3 coldest months. In the second row, for comparison, there is given the *mean* surface direction computed from the pilot-balloon ascents, which are in substantial agreement with the results from the hourly values.

In the last column of the table containing the pilot-balloon results from all observations of both expeditions, is given the difference between the mean direction and the resultant direction, the positive sign indicating that the mean direction is in advance of the resultant direction in the sense of a clockwise rotation; the greatest difference occurs at 8 km., the approximate level of the tropopause, whereas the minimum stability occurs at 4 and 5 km.

The percentage frequencies of the different wind directions at the standard levels for the different seasons are entered in table 15. The bottom row of the table giving the annual average contains the frequencies as computed from the hourly values of the surface wind direction, and has been added in order to show by a comparison of the two sets of surface values how well the pilot-balloon ascents represent average conditions. Corresponding curves are shown in figure 115. The smaller percentage of east winds with the ascents is the result of the fact that the wind from this direction was often accompanied by snow and drift, making a balloon ascent impossible. The higher percentage of southwest winds is, no doubt, due to the fact that the least cloudiness occurred with this direction, thus making it especially favorable for observing the ascents.

Smoothed mean values of the mean velocity with the different wind directions, at standard levels and for the light season, the dark season, and the year, are given in table 16. The annual means are shown graphically for selected levels in figure 116. The smoothing has been

carried out by means of the formula $b = \frac{a+3b+c}{5}$; and the

numbers of observations at the various levels are, of course, the same as in table 15.

The average turning of the wind direction, from the surface up to stated levels and for the different surface wind directions, is given in table 17, in which a clockwise turning is counted as positive and counter-clockwise as negative. The average values were computed by finding, from the individual ascents, the average turning from one level to the next and then adding these differences to obtain the average turning from the surface. The average annual turning of the wind computed in this way is shown in figure 117.

It is of interest to compare the average turning of the wind with altitude at Little America in the Ross Sea area, and that in the Weddel Sea area as determined by Barkow (5) from the pilot-balloon ascents during the drift of the *Deutschland*. The two curves are shown in figure 119.

The mean turning of the wind has also been computed from selected pilot-balloon ascents. The ascents selected were those having the following characteristics: (1) The turning of the wind from the surface in the lower layers is counterclockwise (negative) and attains a fairly constant value (constant wind direction) in the layer from 1 to 2 km.; (2) the wind velocity increases in the lowest layer and attains a reasonably constant value between 1 and 2 km. These conditions were imposed to select, so far as possible, conditions in which there was little variation in the direction and magnitude of the pressure gradient with altitude, when the variations of wind in the lowest layer would be more dependent upon turbulence and friction than upon other factors. It should be noted that in the Southern Hemisphere, the Ekman Spiral gives a counterclockwise rotation of the wind vector with altitude, thus explaining why only the ascents having this property were selected.

The mean velocity and turning of the wind from the surface for the different surface wind directions are given in table 19, where the computation has been carried out for each minute of ascent up to 1,890 m. In table 20 the mean velocity and turning are given for the light season, dark season, and year, regardless of the surface wind directions, also shown in figures 120, 121, and 122.

In table 21 are given the mean velocity and turning of the wind in the lowest layer for low and high surface velocities. The value of 3.6 m. p. s. was used to separate the two velocity groups, since this value was found to be very close to the median of the surface velocities for the selected ascents. These tables can be used in investigating the effects of turbulence and friction from the direction and velocity profiles and for the different wind directions, different seasons, and low and high velocities.

3. TEMPERATURE

Instruments and methods.—The dry-bulb and minimum temperatures were measured by spirit thermometers. The minimum thermometer was used for obtaining both of these temperatures, but an additional spirit thermometer was exposed in the thermometer shelter to serve as a check. At the higher temperatures the spirit thermometer readings were checked against those of a mercurial thermometer. A mercurial maximum thermometer was also used when the temperature was -35° F. or above. Since the thermometers used had a zero correction over most of the temperature range, and corrections of only 0.1° or 0.2° at the very lowest temperatures, no corrections were applied to the readings.

The thermometer shelter was the same type used by the cooperative observers of the United States Weather Bureau (6), and it was set up to the southeast of one of the snow covered buildings of the first expedition and was secured in place by anchoring the supports to wooden posts driven into the snow. The shelters had approximately the same locations on both expeditions. Occasionally during severe blizzards, drifting snow would accumulate inside the shelter and put the thermograph out of action; but these cases were infrequent, and on the whole

the shelter proved quite satisfactory. The thermometers were about 5 feet above the snow surface. The shelter at Bolling Advance Base was mounted on the roof of the hut there, and with certain wind directions it is possible that the temperature readings were influenced by warm air from the chimney which issued from the roof and was connected to a kerosene stove inside the hut. The roof of the hut was level with the surrounding snow surface and was usually covered with several inches of snow.

The thermographs used at Little America were of the standard type used by the United States Weather Bureau and manufactured by Friez, Baltimore. In order to prevent stopping of the clock at low temperatures all the oil was removed by immersion in ether and no oil was ever added afterward, the clockwork functioning perfectly even at the lowest temperatures. During most of the year it was necessary to mix alcohol with the thermograph ink in order to make it flow easily and to prevent freezing. In order to prevent condensation inside the clock, the thermograph drum was never taken indoors to change the record sheet; it was changed either at the shelter or in a nearby tunnel in the snow where the temperature was not much different from that outside. At Bolling Advance Base, a distant recording Foxboro (Mass.) thermograph

was used in which the temperature element, or bulb, was exposed in the instrument shelter and connected by tubing to the recording part inside the building. Although this type of temperature element is not very responsive to rapid fluctuations of temperature, the records seem quite satisfactory for the purpose for which they were intended.

At Little America the thermometers were read three times daily, at 8h, 14h, and 20h (180th meridian time), to the nearest tenth of a degree. At the Advance Base, thermometer readings were made twice daily, usually at 8h and 20h; and the readings were generally to the nearest degree, but sometimes to the nearest one-half degree. The corrections to the thermograph were determined from the thermometer readings at fixed hours, including the maximum thermometer readings when these were available. There was no maximum thermometer at Advance Base; and the only maximum thermometer at Little America during the first expedition was broken after it had been in use but a few months.

The mean monthly and seasonal temperatures at Little America and at Bolling Advance Base are given in table 23. They have been computed by taking the sum of the hourly temperatures for each month, and dividing by the number of hours in the month; similarly for the seasons. The mean values in the other tables have likewise been computed by using hourly values of the different meteorological elements. There are also given the mean monthly temperatures from the combined data of the two expeditions, and they are plotted in figure 123, a smooth curve being drawn to bring out the characteristic features of the annual variation. A curve based on the 6 months of the dark season during which the Advance Base was occupied is also shown.

Here as elsewhere in this report the seasons have been defined as follows:

Summer: December, January, February.
 Autumn: March, April, May.
 Winter: June, July, August.
 Spring: September, October, November.
 Light Season: October, November, December, January, February, March.
 Dark Season: April, May, June, July, August, September.

Thus, the summer season for 1929 is based on the months of January, February, and December 1929, and January 1930, while that for 1934 is based on February (about 19 days), December 1934, and January 1935. The summer season for the combined data is based on all of these months; likewise for the light season.

The results obtained at Framheim during 1911 are also shown in figure 123. The positions are as follows:

Framheim: Latitude $78^{\circ}38' S$; longitude $163^{\circ}37' W$.
 Little America: Latitude $78^{\circ}34'06'' S$; longitude $163^{\circ}55'58'' W$.

Bolling Advance Base: Latitude $80^{\circ}08' S$; longitude $163^{\circ}55' W$.

It is evident that Framheim was not more than several miles distant from the subsequent location of Little America, and it is thus permissible to compare the results at the two stations.

In table 24 are given the mean monthly temperature, wind velocity, and cloudiness for corresponding selected

months, but for the two different years at Little America. The months chosen were those showing the greatest difference in temperature; and it is clear at a glance that when a corresponding month has a higher temperature, it is very definitely associated with higher wind velocities and greater cloudiness.

In table 25 is given the difference between the mean monthly and seasonal temperatures at Little America and Advance Base for the 6 months during which the latter station was occupied, the minus sign indicating that the Advance Base temperature was lower than that at Little America. For the period in question, the mean temperature was always considerably less at Advance Base; and there can be no doubt that this is also characteristic of the other months of the year.

In table 26 are given the mean temperatures with the different wind directions, and with low and high wind velocities, both at Little America and Advance Base. These means have been computed from the hourly values of temperature, wind direction, and velocity. The values for Little America are given for the combined data of both expeditions, and also for the winter and the dark season of 1934 during which observations were made at Advance Base (Meteorological observations were made at Bolling Advance Base from April to September, 1934, inclusive). The division between low and high velocities was arbitrarily set at 12 m. p. h. since this is close to the average annual velocity, but, of course, not necessarily the median. From table 42, which was computed later, it is seen that the median is at about 8 m. p. h., and it would have been more satisfactory if this value had been used to separate the low and high velocity groups; unfortunately, this figure was not available when table 26 was computed.

The result giving the lowest temperatures with northwest winds at Advance Base is quite surprising. Considerable trouble was experienced with the wind vane contacts at this station, making the wind records difficult to interpret in some cases. In these instances use was made of the daily eye observations of wind direction, and it is thought that little, if any, error has resulted.

Table 29 has been constructed to show the effect of cloudiness and wind velocity on temperature; it contains the following data for the four seasons of the year, using combined data: (1) Mean temperature with clear sky and low wind; (2) mean temperature with clear sky and strong wind; (3) mean temperature with clear sky computed from all observations in (1) and (2); (4) mean temperature with cloudy sky and low wind; (5) mean temperature with cloudy sky and high wind; (6) mean temperature with cloudy sky computed from all observations in (4) and (5); (7) the difference in mean temperature with clear sky with low and high winds; (8) the difference in mean temperature with cloudy sky for low and high winds; (9) the difference in mean temperature with clear and cloudy sky. The table also contains: (10) the mean temperature for the season (and year); (11) the difference between the mean seasonal temperature (and yearly mean) and the mean temperature (1), (2), (4) and (5). The mean values (1), (2), (3), (4), (5), and (6) have all been computed from hourly values of wind velocity, temperature and cloudiness. Since hourly observations of cloudiness were not made at Advance Base, no table has been constructed for that station.

¹ On board ship in Bay of Whales.² First 15 days of February on board ship in Bay of Whales.³ Last 13 days of February at Little America.⁴ From combined observations for February on board ship in Bay of Whales and at Little America.⁵ Includes observations on board ship in the Bay of Whales.⁶ According to the thermograph records the lowest recorded temperature at Advance Base was -83° F. at 4h on July 21. Although there was no reading of the minimum thermometer at 8h on this date, the minimum thermometer reading at 20h of the same day is given as -78° F.; following the customary procedure, the recorded value of -83° F. has therefore been corrected to -78° F. (G. G.)

⁵ Includes observations on board ship in the Bay of Whales.

⁶ For the last 19 days in February.

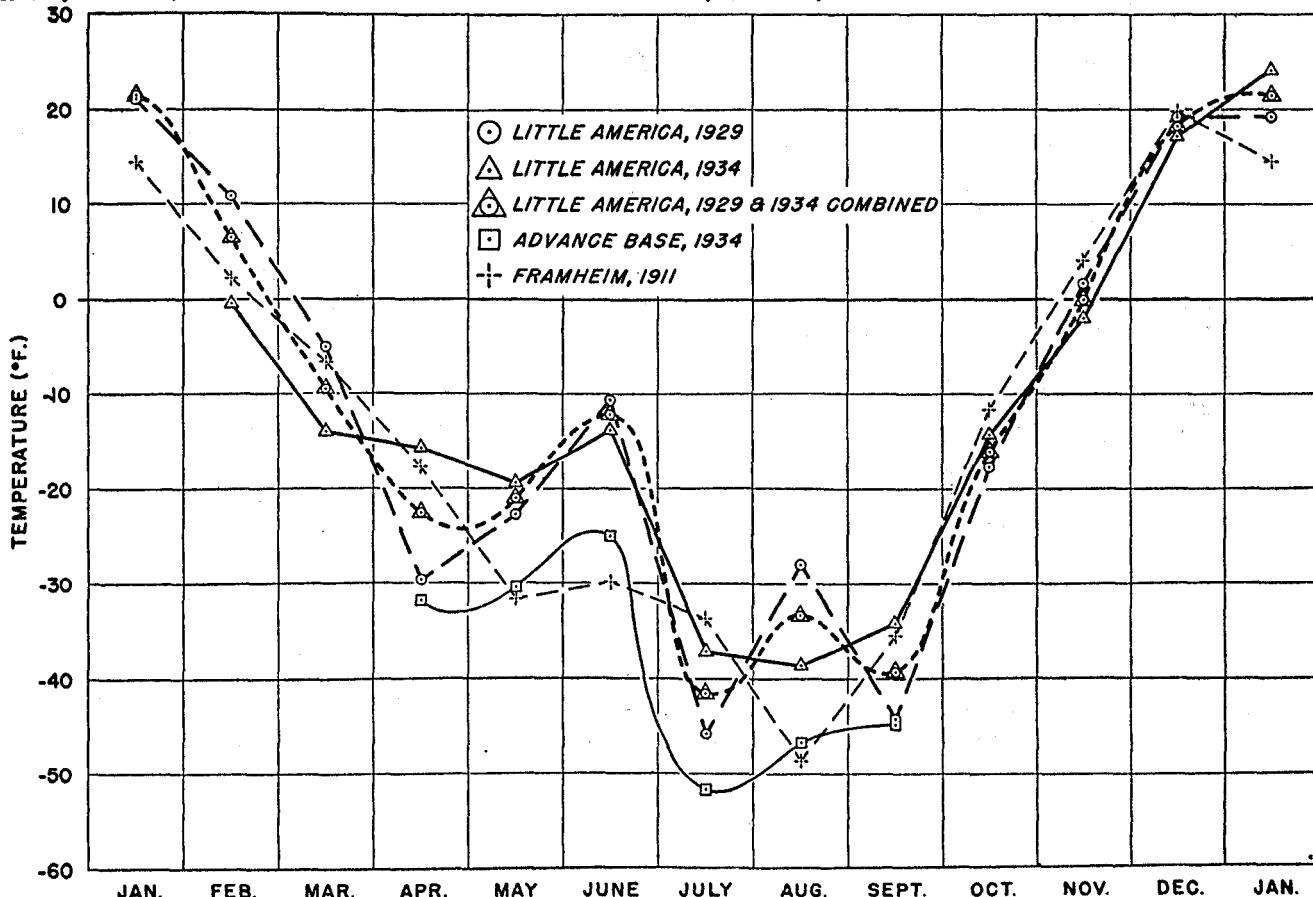

FIGURE 123.—Annual variation of temperature at Little America, Framheim, and Bolling Advance Base.

4. PRESSURE

The mercurial barometers used on the expeditions were of the standard type used by the United States Weather Bureau and described in (7). Each expedition had two of these barometers; and on the second expedition three additional barometers were loaned by the Precision Instrument Co. of Philadelphia, Pa. Before leaving the United States, each instrument was compared with a standard barometer and the instrumental error determined.

Upon reaching Little America, comparative readings were made to detect any errors which might have resulted from the long journey, but owing to the very careful handling no indication of error was found. The barometer with the smallest instrumental error was used as a standard for the daily observations and was checked at intervals by comparative readings with the other instruments. The results of these comparisons did not justify any change in the instrumental correction to the standard.

A mercurial barometer was very carefully packed and sent along for use at the Bolling Advance Base, but was broken either while enroute or while the base was being established, so that the pressure readings there had to be made with an aneroid barometer which had been carefully checked and adjusted before it left Little America. The barograph at Advance Base was corrected by use of the aneroid readings, which could be made to the nearest 0.01 inch. At Little America the barograph was corrected by means of the readings of the mercurial barometer, which were made three times daily and to the nearest 0.001 inch.

On both expeditions the barometers at Little America had identical positions and were 30 feet above sea level. The pressures at this station have been reduced to sea level by using this figure for the elevation, and the current surface temperature, and by assuming the mean temperature of the air column to be the same as the surface temperature. The corrections computed in this way vary from 0.03 to 0.04 inch, depending on the temperature and pressure. All values of pressure given for Little America have been reduced to sea level, 32° F., and standard gravity; those for Advance Base have not, and are simply station values.

Owing to the uncertainty in the elevation of the Advance Base, and also the uncertainty of how the pressure there is best reduced to sea level, it was thought preferable, at least as a first attempt, to use the synoptic charts given by Simpson (20) for the Ross Sea and Ross Shelf Ice areas to compare the sea level pressure at Little America and Advance Base and thus get some idea as to the probable pressure gradient southward. The charts given by Simpson are based mainly on daily observations at Cape Adare, Cape Evans, and Framheim, Framheim being only a few miles distant from the subsequent location of Little America. The sea level pressure at the position of Advance Base was taken from the charts by interpolation between the isobars, while the pressures for Framheim are the values directly observed at the same time. This has been done for all of the synoptic charts and the mean values and their differences are given in table 31A.

Tables 32 to 36 comprise the different pressure tables. Table 35 was computed from hourly values of pressure and wind direction in order to see if any relation existed between wind direction and pressure. Table 36 contains

the mean pressure for each 10-day period for the 2 years at Little America and 6 months at Bolling Advance Base. These values may be of some use in the study of pressure surges in the Antarctic.

TABLE 31A.—*Mean sea-level pressure at Framheim and at the position of Advance Base, based on Simpson's synoptic charts*

5. WIND

Continuous automatic records of wind direction and velocity were made at Little America and Advance Base. At both stations the height of the anemometer above the snow surface was about 15 feet, and at Little America the exposure was identical on the two expeditions. Various results obtained from the automatic records are given in the following tables; 4-cup anemometers were used on the first expedition, and 3-cup on the second. All recorded velocities have been corrected according to the following table of corrections:

Table of corrections applied to indicated velocities

[Corrections applied to wind velocities determined by anemometers; correction added when the sign is plus and subtracted when the sign is minus]

By 3-cup anemometer, m. p. h.	By 4-cup anemometer, m. p. h.	Correction in whole miles per hour

	111 to 114	-27
	115 to 117	-28
	118 to 121	-29

Table of corrections applied to indicated velocities—Continued

By 3-cup anemometer, m. p. h.	By 4-cup anemometer, m. p. h.	Correction in whole miles per hour
193 to 200	122 to 125	-30
	126 to 128	-31
	129 to 132	-32
	133 to 136	-33
	137 to 140	-34
	141 to 143	-35

In table 37 the absolute maximum velocity is defined as the velocity corresponding to the mile of wind passage in the shortest time. The prevailing direction is determined from the hourly values of wind direction for the period in question and is defined as that direction for which the hourly values have the greatest frequency. The mean wind velocities with the different wind directions given in table 38 have likewise been computed from hourly values of direction and velocity.

Tables 39, 40, and 42 have all been computed from hourly values. In table 40 the mean direction, resultant direction and velocity and stability have been computed in the same manner as described above for the pilot-balloon ascents. Table 41 gives the mean maximum velocity with the different wind directions, computed from the values of the maximum direction and velocity for each day. The percentage frequency of cases when the daily maximum occurred with the different directions is also given. The number of days in each month with light and strong winds is given in table 41A, in which a strong wind was arbitrarily defined as that in which the mean daily velocity was equal to or greater than 20.0 miles per hour, and a light wind as that in which the mean velocity for the day was less than or equal to 5.0 miles per hour. There is also given the number of days when the absolute maximum velocity was equal to or greater than 30.0 miles per hour. The definition of maximum velocity has already been given above. Table 42, which was computed from hourly values, gives the frequency distribution of the different wind velocities and was computed in order to compare the wind characteristics at Little America with those at McMurdo Sound.

6. CLOUDS

The results of the cloud observations are given in tables 43 to 52. In table 47 is given the total number of observations of the different cloud types made three times daily as a part of the regular daily surface observations. Percentage frequencies based on these numbers are given in table 48. The number of fogs includes light as well as dense fog. Stratus is by far the most frequent cloud form, except in summer when the StCu form occurs with about the same frequency. Cumulus occurs occasionally in the summer when there is strong convection over the open water to the north. The mean direction of the

different cloud forms, based on the regular daily cloud observations mentioned in connection with table 47, is given in table 49.

In table 50 are given the altitudes of the different cloud forms as determined from individual pilot-balloon ascents; mean values are entered in table 51. Since, in the Antarctic, the *mean* direction of cloud motion has frequently been used to represent the average wind direction at upper levels, table 52 has been constructed to show how the mean direction of cloud motion as computed from the eye observations differs from the mean and resultant directions computed from the pilot-balloon ascents, that is, from the average wind direction at these levels.

7. RELATIVE HUMIDITY, PRECIPITATION AND VISIBILITY

The mean relative humidity for the different months and seasons is given in table 53 and has been computed from the hourly values of humidity as determined by the registration of the hair hygrograph. The poor behavior

of the hair element at low temperatures is well known and consequently no great accuracy can be claimed for the values given, especially in the winter months.

The number of days in each month with different forms of precipitation and also with dense fog is given in table 54. The large number of days with snowfall should not

be interpreted as indicating correspondingly large amounts of snowfall, since in many of these cases the snowfall was very light, consisting of very small flakes and not amounting to more than a trace. The mist referred to was extremely light, so light, in fact, that it was just barely perceptible. Notes concerning this will be found in the volume of observational data. Showers of minute particles of clear ice, usually having an elongated form and sometimes referred to as ice spicules or ice needles (referred to simply as ice crystals here), were of fairly frequent occurrence and were often present with a perfectly clear sky.

In 1929, observations of visibility were made three times daily as part of the regular surface observation, and the mean values for the different months and seasons are given in table 55. The scale of visibility used was as follows:

Visibility scale

Scale	Descriptive term	Limiting distance (meters)
0	Dense fog—prominent objects not visible at-----	50
1	Very bad—prominent objects not visible at-----	200
2	Bad—prominent objects not visible at-----	500
3	Very poor—prominent objects not visible at-----	1,000
4	Poor—prominent objects not visible at-----	2,000
5	Indifferent—prominent objects not visible at-----	4,000
6	Fair—prominent objects not visible at-----	10,000
7	Good—prominent objects not visible at-----	20,000
8	Very good—prominent objects not visible at-----	50,000
9	Excellent—prominent objects visible beyond-----	50,000

Table 54 also includes values for the total snowfall for each month in 1939. In the Antarctic most of the snow-

fall occurs with fairly high winds, making the measurement as well as any estimate of the amount of snowfall difficult since the falling snow is mixed with drifting surface snow; the difficulty is further enhanced by the tendency of the wind to sweep the newly fallen snow along the surface. In these instances the amount of snowfall was "estimated" as closely as possible by taking into account its intensity and duration. When the snowfall occurred with light winds, the depth of the newly fallen snow on the surface was measured directly (without the use of a snow gage) and the amounts given in these instances (see (1) table 24) can be regarded as quite accurate. Owing to the difficulty of estimating the amount of snowfall, it is hard to say how much weight can be given to the monthly values given in the table; H. T. Harrison who made the estimates as well as the measurements, is of the opinion that the daily amounts when determined by estimate may in some cases differ from the true fall by as much as 50 percent, but that the relative snowfall by months can be accepted as fairly accurate. From his own experience the writer is of the opinion that, if anything, the values given are too large; at least, over a period of a year, there is certainly no *accumulation* of snow at all comparable with the values given in the table. In August 1934, the writer planted two small brass rods at two widely separated locations where the barrier was flat and smooth. These were inspected five months later in January and each showed an accretion to the surface of about 6 inches. This accretion, of course, represents the combined effect of drift and snow, and just how much of each it is impossible to state. The above amount if extrapolated linearly over a 12 months' period would give an annual amount of 14 inches.

8. METEOROLOGICAL CONDITIONS DURING "CLEAR"
PERIODS AT LITTLE AMERICA

One of the most difficult and important duties confronting the polar expedition meteorologists is the forecasting of periods of good flying weather for the various expedition aviation activities. This is especially difficult in the Antarctic, where the meteorologist is forced to estimate future weather conditions from the meteorological observations at a single station. Because of this difficulty it was thought that a statistical study of the periods of favorable flying weather might be of some value and the following tables were prepared for the purpose of investigating the occurrence and frequency of periods of weather favorable for flying, as well as the meteorological conditions prevailing during such periods.

Of the various hazards connected with polar flying, the first and foremost is that of clouds; and it therefore falls upon the polar meteorologist to predict periods of clear sky, both as to time of occurrence and as to length of period. Cloudy skies not only produce poor light conditions, making it difficult to get satisfactory aerial mapping photographs and to use navigation instruments (such as sun compass), but also when there is a stratus or thick altostratus overcast it is usually very difficult to distinguish a horizon—the snow surface and cloud layer seem to fuse into one without any visible line of separation or horizon—making an accurate judgment of distance and altitude difficult for the pilot, and landing, forced or otherwise, a dangerous undertaking. There is, in addition, the usual hazard of having to come down through a low overcast

which may have formed during the flight, and make a forced landing on terrain of unknown elevation. Finally, it is important to have clear conditions, not only during the flight, but also when the plane returns to the base, since in addition to the difficulty of landing with poor horizon conditions attending overcast skies mentioned above, there is the added difficulty of finding the base itself if the plane is forced to fly above a low stratus overcast.

At Little America, extended periods of absolutely cloudless sky are not very frequent; and since airplane flights can be successfully carried out even though the sky is not absolutely clear, the following definition of clear period has been used, based on the usual cloudiness scale, 0-10, referring to the number of tenths of sky containing cloud:

There shall not be more than five-tenths of upper clouds, such as Ci, CiSt, and CiCu; there shall not be more than two-tenths of intermediate clouds, such as ASt and ACu; there shall not be more than one-tenth of lower clouds, such as St, StCu, and Cu,

Using this definition of a clear period, table 56 has been constructed, which gives the beginning, ending, and length of the periods, and the pilot-balloon, kite, and airplane ascents made during the periods. There are also given mean values of the various meteorological elements during the periods as computed from hourly values, and the departures of these means from the monthly means. Only periods of 12 hours or more duration are given, since clear periods shorter than this are probably not of much value in planning extended flights.

In column 15 of table 56 is entered the type of pressure variation association with each period; and the amount of this variation is given in column 2. For cases when the pressure was rising, falling, or steady, this is simply the amount of pressure fall or rise from the beginning to the end of the period. In the case when the pressure rose and then fell, the pressure change given was obtained by finding the amount of pressure rise from the beginning of the period to time of highest pressure and adding this to the amount of pressure fall from this point to the end of the period without regard to sign, thus giving the *total* variation in the pressure, and is indicated by a \pm sign. In cases where the pressure fell and then rose, the pressure change was computed in a similar manner and is indicated by a \pm sign.

Although the definition of clear weather used was quite liberal, allowing a maximum total cloudiness of eight-tenths, it is seen that the actual cloudiness during the periods turns out to be quite small. Nearly all of the periods have a mean cloudiness of less than one-tenth (1.0); and there are only a few with two-tenths or more, the greatest being 3.8 for period no. 47. The clear periods thus turn out to have much less cloudiness than one might expect from the definition used; and although the tables were originally constructed for the purpose of studying conditions favorable for aviation activities, it is thought that they are at the same time quite suitable for use in connection with any other meteorological studies relating to clear weather.

The clear periods in table 56 have been combined by months and the results are given in table 57.

It was found that clear weather could occur with almost any type of pressure change. The pressure changes have been separated into the following five types:

Pressure rising.

Pressure falling.

Pressure steady.

Pressure rising and then falling.

Pressure falling and then rising.

In table 61 are given the different clear periods during which the change in pressure was of one of the above types, and also the length of clear weather and amount of pressure change associated with each type.

The results of pilot-balloon ascents made during clear periods have been evaluated and are given for the four seasons and for the year in table 62, the north-south and east-west components referring to the resultant velocity. The percentage frequency and mean velocity of the different wind directions at standard levels during these periods are given in tables 63 and 63A; while the mean turning of the wind from the surface up to given levels during clear periods is shown in table 64.

The results of pilot-balloon ascents made during the different types of pressure change associated with the clear periods have been computed and are contained in tables 65 to 71. For the periods with pressure rising and then falling, the computation was made separately for the interval with rising pressure and that with falling pressure, and similarly for periods with pressure falling and then rising. This was done since it was anticipated that upper level wind conditions with rising pressure would differ from those with falling pressure. In order to see, if possible, what changes take place in the upper level winds during the transition to a clear period, the results have also been computed for the 24- to 36-hour interval preceding the clear periods associated with the different types of pressure change and are given in tables 72 to 76.

TABLE 61.—Pressure changes during clear periods

	Type of pressure change				
	Pressure rising	Pressure falling	Pressure steady	Pressure rising and then falling	Pressure falling and then rising
Number of period-----	2, 6, 10, 24, 26, 30, 31, 35, 39, 42, 48, 50, 53, 59, 62, 63, 71, 79, 80, 84, 86, 87, 88, 89, 96, 104, 105, 114, 115, 117.	1, 3, 5, 8, 11, 12, 13, 18, 20, 27, 28, 29, 40, 41, 44, 45, 46, 51, 54, 55, 56, 57, 60, 74, 76 (Part), 77, 78, 85 (Part), 90, 91, 93, 94, 95, 99, 100, 101, 107, 108, 110, 111, 112, 116.	4, 7, 15, 17, 19, 23, 25, 33, 43, 47, 52, 58, 64, 65, 66, 67, 69, 70, 72, 75, 81, 83, 106, 109, 113, 118.	9, 14, 21, 22, 36, 38, 49, 61, 68, 76 (Part), 85 (Part), 92, 103.	16, 32, 34, 37, 73, 82, 97, 98, 102, 119.
Number of cases-----	30-----	42-----	26-----	12-----	10.
Maximum length of clear period.	54 hours, No. 84-----	82 hours, No. 101-----	80 hours, No. 75-----	167 hours, No. 22-----	121 hours, No. 37.
Average length of clear period.	27.3 hours-----	34.5 hours-----	28.7 hours-----	59.1 hours-----	58.2 hours.
Average pressure change during clear periods.	0.273 inch-----	-0.248 inch-----	0.062 inch ² -----	0.570 inch ¹ -----	0.662 inch ¹
Average departure of the mean pressure during clear periods from the monthly mean.	0.033 inch-----	0.049 inch-----	0.126 inch-----	0.215 inch-----	-0.115 inch.

¹ Obtained by adding the amount of pressure rise and the amount of pressure fall without sign, thus giving average total variation.² Mean obtained without regard to sign, thus giving average total variation.
